# Description

The purpose of this document is to explain how my obstacle detection and avoidance algorithm works and how it navigates the Autonomous Ground AGV (AGV).

The idea is simple: If an object is detected, rotate until its cleared. Once cleared continue moving to goal.

The algorithm depends on two ROS topics types: Lidar and Odometry. For each topic, we subscribe a callback function, cbLidar and cbOdometry.

**cbLidar** is responsible for detecting obstacles and moving the AGV until the object is not detected.

Using the lidar data, it reads the ranges. When it detects a short range in the direction of the front of the AGV, it takes the following actions:

- Sets a global flag that an obstacle is detected.
- Stop the AGV.
- Rotate the AGV.

Once it stops reading short ranges from the lasers in front of the AGV, it takes the following actions:

- Move the AGV a short distance in the current direction.
- Set global flag that an obstacle is NOT detected.

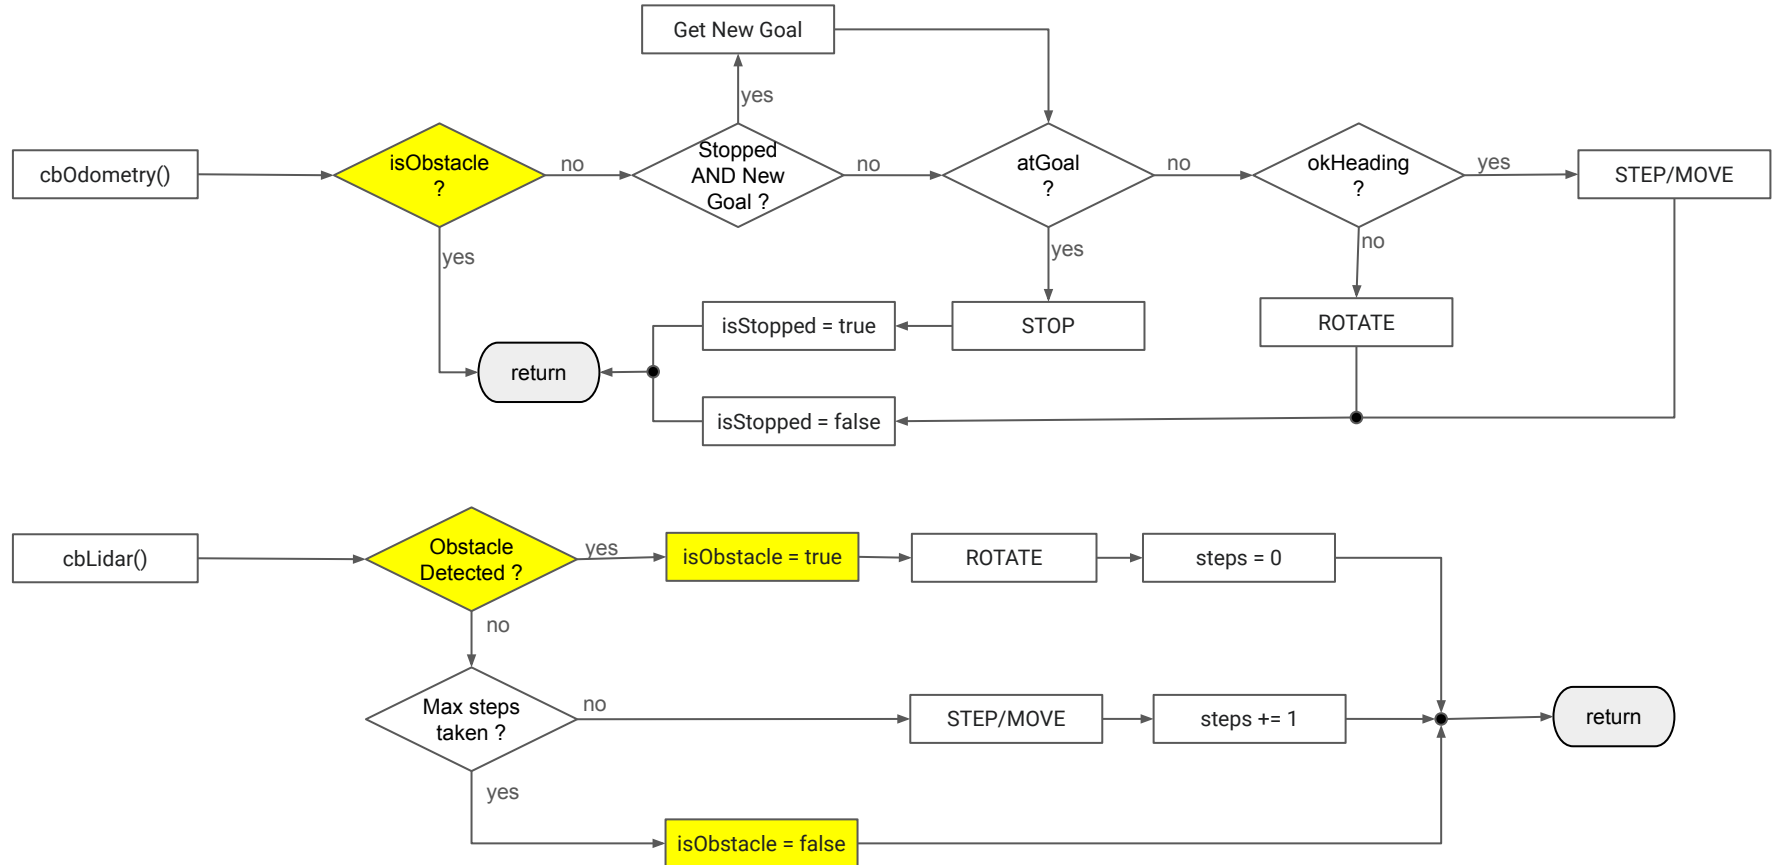

**cbOdometry** is responsible for calculating the heading to our goal and move the AGV in that direction. It uses the pose quaternion to calculate the euler angles and get the yaw of our AGV. It also uses the pose position and the goal position to calculate the “angle-to-goal”. Using this angle-to-goal and the yaw value, we can calculate if we are heading in the correct direction.

Once we have these values, it takes the following actions: Stop, Spin, or Move.

- Stop  
Pose position and goal are the approximately the same location.
- Spin  
The angle difference between angle-to-goal and yaw is greater than 0.5 radians.
- Move  
Default action if we are not stopping nor spinning. In other words, we are heading in the correction direction, so move.

**Note:** If an obstacle is detected by the cbLidar, the cbOdometry function will return immediately after it gets called. We don't want both callbacks controlling the AGV at the same time.

# Data Flow

# Errors / Assumptions

## **Odometry Error**

This algorithm is only using odometry to calculate position and direction. Overtime, odometry builds error and this will affect the navigation of the AGV. This error can come from

- Incorrect wheel geometry settings (radius, pose)
- Wheel slippage, like when the vehicle rotates in place.

A potential solution to correct these errors is by using an IMU. IMU gives us the correct orientation of the AGV, so this can correct the heading. Using the accelerometers, we can detect if we are moving. And using the gyroscopes, we can detect rotations. So using these information we can detect wheel slippage or rotations.

## **Detection Field of View**

Although the lidar has a 360 scan view, the algorithm only uses the ranges from the front half of the AGV. The algorithm only detects and avoids obstacles when driving forward. In addition, if a dynamic object (ie a person) were to move towards the back of the AGV, although it could detect it, the algorithm will not take any action. It assumes the other moving object will “see” the AGV and avoid it.
